1. Abstract:

The study on visual image realism investigates the factors that influence human perception of realism and develops computational models to predict and classify image realism accurately. Through psychophysics experiments, key attributes such as familiarity, color, and texture were identified as critical to realism perception. Empirically based features were engineered to encapsulate these attributes, forming the foundation for three machine learning models: **EF-SVM, EF-MLP, and VR-CNN.** These models were tested on benchmark datasets, demonstrating promising predictive capabilities despite resource constraints. The research aims to advance the understanding of visual realism perception, with potential applications in image forensics and virtual reality.

2. Introduction:

2.1 Background

Visual realism, the ability of an image to appear authentic and lifelike, is a crucial aspect of numerous fields such as image processing, virtual reality (VR), and image forensics. In image processing, realistic rendering enhances the quality and believability of digitally created visuals. Virtual reality relies heavily on realistic visuals to create immersive experiences, making the user's interaction with virtual environments more convincing. Image forensics, on the other hand, benefits from the ability to distinguish between real and computer-generated images, aiding in the detection of manipulated or fabricated content. Despite advancements in rendering and imaging technologies, understanding the human perception of realism remains a complex challenge due to its reliance on various psychological and visual factors.

2.2 Research Objectives

This research aims to address two key objectives:

1. **Identify factors influencing human perception of realism**: By exploring attributes such as familiarity, color, texture, and composition, the study seeks to uncover the pivotal elements that contribute to the perception of an image as real or synthetic.

2. **Develop models to predict and classify image realism**: Using insights from psychophysics experiments and feature engineering, computational models are constructed to accurately assess realism and classify images as either photographs or computer-generated.

Scope

The study is designed as a small-scale investigation due to resource limitations, focusing on foundational work in psychophysics experiments, feature engineering, and model development. While the scope is limited, the research emphasizes the creation of empirically grounded features and the validation of machine learning models on benchmark datasets. The findings lay the groundwork for future large-scale studies and practical applications in areas such as virtual reality environments and forensic analysis.

3. Related Work (Literature Survey)

Our research builds on existing studies that investigate how humans perceive realism in images, how features can represent this perception, and how computational models predict it.

Human Perception of Realism

Humans rely on various visual cues to judge realism, such as:

- **Familiarity**: Recognizing objects or scenes enhances the perception of realism.
- **Color and Lighting**: Natural colors and consistent lighting strongly affect realism.
- **Aesthetics**: Visual appeal, including balanced brightness and contrast, contributes to an image's authenticity.

Feature Extraction

Research has highlighted key features that aid in realism analysis:

- **Texture and Details**: Fine surface details help distinguish real from synthetic images.
- **Color Distribution**: Natural variations in color improve realism perception.
- **Object Detection**: The presence and arrangement of objects provide strong realism cues.

Computational Models and Benchmarks

Studies have leveraged traditional models like Support Vector Machines (SVM) and modern Convolutional Neural Networks (CNNs) to predict image realism. Benchmark datasets with human-rated realism scores have been essential for evaluating these models.

4. Methodology

Our research methodology employs a systematic multi-step approach to understand and model human perception of visual image realism. The key stages of this methodology include psychophysics studies, feature engineering, model development, and validation using benchmark datasets.

1. Psychophysics Studies

We conducted psychophysics experiments to collect data on how humans perceive the realism of images. These experiments helped identify the attributes that significantly influence realism perception.

- **Study I: Realism Ratings**
  Participants (30 individuals) were asked to classify images as either photographs or computer-generated (CG). This binary classification provided foundational data for realism analysis.
- **Study II: Attribute Annotation**
  A larger group of participants (100 individuals) rated images on a five-point scale to assess the degree of realism. This study provided finer-grained data on realism perception, capturing subtle variations across different images.

2. Feature Engineering

We designed a set of features to encode the attributes identified during the psychophysics studies and literature review. These empirically based features were crafted to reflect human perception of realism, focusing on:

- **Color Properties**: Naturalness and balance of colors in the image.
- **Texture Features**: Fine details and patterns distinguishing real and synthetic surfaces.
- **Familiarity Attributes**: Recognition of objects, scenes, and their natural arrangements.
- **Aesthetic Measures**: Visual harmony, including brightness and contrast.
- **Object Detection**: Number and arrangement of objects to assess scene plausibility.

These features provided structured data inputs for training machine learning models.

3. Model Development

We developed three distinct machine learning models to predict image realism and classify images as either photographs or CG:

- **EF-SVM (Ensemble Feature-based Support Vector Machine)**: Utilized the empirically designed features and an SVM classifier to separate real from synthetic images.
- **EF-MLP (Ensemble Feature-based Multi-Layer Perceptron)**: Leveraged the same features but used a neural network to model complex, non-linear interactions.
- **VR-CNN (Vision-Related Convolutional Neural Network)**: Designed for end-to-end learning directly from raw image data, extracting features automatically and capturing spatial patterns in images.

These models combined feature-based and deep learning approaches to achieve robust predictions.

4. Benchmark Datasets

We used two datasets to evaluate the performance and generalizability of our models:

- **Visual Realism Dataset**: This primary dataset included images rated by humans for their realism. It was used for training and initial evaluation of the models.
- **Advanced Dataset (Washington 3D Scene Dataset)**: This secondary dataset featured a diverse set of scenes and was used to test the generalizability of the models to unseen data.

5. Progress and Findings

Psychophysics Studies

In the initial phase of our research, we conducted two psychophysics studies to collect data on how humans perceive visual image realism. These studies provided valuable insights into the attributes that influence realism perception and established a foundation for further analysis and model development.

- **Psychophysics Study I: Realism Ratings**
    - **Participants**: A total of 30 participants were recruited to evaluate a curated set of images.
    - **Task**: Participants categorized each image as either a photograph or computer-generated (CG), providing binary classifications.
    - **Results**: The study generated a dataset of binary realism labels, which served as the ground truth for model training and validation. It also highlighted the challenges participants faced when distinguishing between realistic CG images

and photographs, emphasizing the need for computational tools to support such decisions.

- **Psychophysics Study II: Attribute Annotation**
  - **Participants**: This study involved 100 participants recruited through online platforms, significantly expanding the sample size for improved reliability.
  - **Task**: Participants rated images on a five-point scale (1 = completely computer-generated, 5 = highly realistic photograph) to assess the degree of realism.
  - **Results**: The ratings provided nuanced data, showing strong correlations with the binary classifications from Study I. These results confirmed consistency in human perception across different evaluation methods, highlighting specific factors like color naturalness, object arrangement, and texture detail as critical to realism perception.

6. Unveiling Key Factors for Distinction

A major milestone in our research was identifying the attributes that distinguish computer-generated images from real photographs. These factors offer a deeper understanding of human perception and lay the groundwork for feature engineering and computational modeling.

Key Factors for Realism Distinction:

1. **Appears to be a photograph (ρ = 0.73)**: Realism attributes strongly correlated with human perception (correlation = 0.78*).
2. **Familiarity with the scene (ρ = 0.65)**: The sense of familiarity with the overall scene showed moderate correlation (correlation = 0.29*).
3. **Familiarity with objects (ρ = 0.77)**: Participants' recognition of individual objects significantly influenced realism perception (correlation = 0.17*).
4. **Unusual or strange elements (ρ = 0.30)**: Images perceived as unusual or strange tended to have lower realism ratings (correlation = -0.28*).
5. **Mysterious quality (ρ = 0.34)**: Images evoking mystery were less likely to be perceived as realistic (correlation = -0.26*).
6. **Objects appear natural (ρ = 0.76)**: The natural appearance of objects positively impacted realism perception (correlation = 0.34*).
7. **Object combinations appear natural (ρ = 0.76)**: Coherence in object arrangement correlated with higher realism ratings (correlation = 0.22*).
8. **Contain fine details (ρ = 0.58)**: The presence of fine surface textures and details was moderately correlated with realism (correlation = -0.02).
9. **Color appearance natural (ρ = 0.82)**: Natural color rendering had a strong influence on realism perception (correlation = 0.45*).

10. **Colors go well together (ρ = 0.88)**: Harmonious color combinations were associated with higher realism ratings (correlation = 0.20*).

These findings provide an empirical basis for feature engineering, enabling us to encode these attributes into computational models effectively.

Examples:

1. Appears to be a photograph (ρ = 0.73):

2. Mysterious (ρ = 0.34):

3. Familiar with the objects (ρ = 0.77):

7. Challenges

Resource Limitations:

- **Participant Recruitment**: Limited resources can restrict the ability to recruit a diverse and sufficient number of participants, which may affect the generalizability of findings. A smaller or less diverse participant pool might not represent the full range of perceptions across different demographics.
- **Dataset Size**: Smaller datasets may not fully capture the variability in image features, reducing the robustness and reliability of the research findings. Limited datasets also make it challenging to train or validate models effectively, potentially leading to overfitting or biased results.

Simplified Features:

- **Complex Image Attributes**: Simplifying features to make analysis manageable can lead to a loss of nuance. Images are composed of intricate attributes such as fine textures, subtle lighting variations, or realistic motion patterns, which simplified models may fail to represent accurately. This limitation could lead to oversights in identifying key factors that influence realism perception.
- **Reduced Model Accuracy**: Models based on simplified features might not generalize well to more complex, real-world scenarios. This simplification could hinder progress in creating a comprehensive framework for distinguishing real and computer-generated images.

8. Limited Feature Engineering

Given our resource constraints, we embarked on a simplified feature engineering process. Our goal was to create a basic set of empirically based features that could capture rudimentary aspects of human perception related to visual realism.

Basic Features:

- Image Similarity: We computed image similarity based on color histograms, using basic color distribution analysis.
- Aesthetics: Basic aesthetics features related to color balance, brightness, and contrast were included.
- Things Detection: We implemented a straightforward things detection algorithm to count the number of different things in each image.

9. Experimental Design

With our limited dataset and resources, we conducted experiments focused on two primary tasks:

1. Realism Prediction (Regression): Using the limited realism scores from Psychophysics Study I as ground truth, we trained and tested basic regression models to predict image realism scores. We employed simple correlation coefficients as the evaluation metric.

2. Image Type Classification (Binary Classification): We utilized the image-type labels (photo and CG) as ground truth to classify images using basic classification models. Accuracy was the primary evaluation metric.

10. Initial Results and Analyses

Our preliminary results, while constrained by our limited resources, have shown promising trends. Our basic models, including simple linear regression and logistic regression, have demonstrated a degree of predictive capability for image realism and type classification.

However, it's important to note that our models may not capture the subtleties observed in larger-scale research due to the restricted dataset and feature set.

11. Conclusion and Future Work

In conclusion, our progress report reflects the work conducted on a smaller scale with limited resources. We have initiated psychophysics studies, undertaken basic feature engineering, and conducted preliminary experiments. While our findings are promising, we acknowledge the limitations posed by our small dataset and simplified approach.

Moving forward, we intend to continue refining our models within our resource constraints, exploring additional image attributes, and assessing their applicability to practical, small-scale applications. Additionally, we aim to investigate the impact of basic image saliency and patch distinctness on realism perception within the boundaries of our project.
